HIGHLIGHTS

• Adult Fmr1 KO mice show reduced pre-pulse inhibition of acoustic startle.
• Pre-pulse inhibition in Fmr1 KO mice is normal if MMP-9 is genetically reduced.
• MMP-9 is involved in sensory gating.
• MMP-9 may be a potential target for sensory hypersensitivity symptoms in FXS.

ABSTRACT

Sensory processing abnormalities are consistently associated with autism, but the underlying mechanisms and treatment options are unclear. Fragile X Syndrome (FXS) is the leading known genetic cause of intellectual disabilities and autism. One debilitating symptom of FXS is hypersensitivity to sensory stimuli. Sensory hypersensitivity is seen in both humans with FXS and FXS mouse model, the Fmr1 knockout (Fmr1 KO) mouse. Abnormal sensorimotor gating may play a role in the hypersensitivity to sensory stimuli. Humans with FXS and Fmr1 KO mice show abnormalities in acoustic startle response (ASR) and prepulse inhibition (PPI) of startle, responses commonly used to quantify sensorimotor gating. Recent studies have suggested high levels of matrix metalloproteinase-9 (MMP-9) as a potential mechanism of sensory abnormalities in FXS. Here we tested the hypothesis that genetic reduction of MMP-9 in Fmr1 KO mice rescues ASR and PPI phenotypes in adult Fmr1 KO mice. We measured MMP-9 levels in the inferior colliculus (IC), an integral region of the PPI circuit, of WT and Fmr1 KO mice at P7, P12, P18, and P40. MMP-9 levels were higher in the IC of Fmr1 KO mice during early development (P7, P12), but not in adults. We compared ASR and PPI responses in young (P23-25) and adult (P50-80) Fmr1 KO mice to their age-matched wildtype (WT) controls. We found that both ASR and PPI were reduced in the young Fmr1 KO mice compared to age-matched WT mice. There was no genotype difference for ASR in the adult mice, but PPI was significantly reduced in the adult Fmr1 KO mice. The adult mouse data are similar to those observed in humans with FXS. Genetic reduction of MMP-9 in the Fmr1 KO mouse resulted in a rescue of adult PPI responses to WT levels. Taken together, these results show sensorimotor gating abnormalities in Fmr1 KO mice, and suggest the potential for MMP-9 regulation as a therapeutic target to reduce sensory hypersensitivity.

1. Introduction

Fragile X syndrome (FXS) is a leading genetic cause of intellectual disability and autism. In conjunction with learning, anxiety, communication, and social deficits (Hatton et al., 2006), individuals with FXS are often hypersensitive to sensory stimuli. FXS is linked to a genetic mutation in the X chromosome with varying degrees of severity, due to the expansion of CGG repeats in the Fragile X mental retardation-1 (Fmr1) gene (Snow et al., 1993). If the repeated sequence exceeds ~ 200 repeats, this can lead to a full mutation and methylation of the Fmr1
gene which in turn causes transcriptional suppression of the \textit{Fmr1} gene and the loss of Fragile X mental retardation protein (FMRP). Loss of FMRP has been associated with abnormal protein synthesis, particularly those involved with synaptic plasticity and maturation (Huber et al., 2002; Sidorov et al., 2013).

Debilitating sensory hypersensitivity is a common symptom in humans with FXS (Tsirouis and Brown, 2004), manifesting as intolerance to even mild sensory inputs. An animal model of FXS, the \textit{Fmr1} knock out (\textit{Fmr1} KO) mouse, shows many of the core abnormalities of FXS including sensory hypersensitivity (Rais et al., 2018; Sinclair et al., 2017). Sensorimotor gating is a low-level (pre-attentive) sensory filtering mechanism to reduce sensory overload reaching cortical areas. Abnormal sensorimotor gating may contribute to hypersensitivity in autism spectrum disorders (Scott et al., 2018), including FXS (Sinclair et al., 2017). Acoustic startle response (ASR) and prepulse inhibition (PPI) of ASR are behavioral outcomes used to test sensorimotor gating in humans and rodents. The circuits underlying these behaviors are present in the brainstem and midbrain of the auditory system. FMRP, the protein product of \textit{Fmr1} gene, is expressed across all levels of the central auditory system, including strong expression in the cochlear nucleus and other regions of the brainstem (Zorio et al., 2017). Abnormal functions of these regions in \textit{Fmr1} KO mice have been reported (Garcia-Pino et al., 2017; Mott and Wei, 2014; Wang et al., 2018) and both humans with FXS and \textit{Fmr1} KO mice show altered ASR and PPI responses (human: Frankland et al., 2004; Yuhas et al., 2011; Hessl et al., 2019; mouse: Chen and Toth, 2001; Nielsen et al., 2002; Renoux et al., 2014; Yun et al., 2006).

One of FMRP’s translational targets is matrix metalloproteinase-9 (MMP-9), an endopeptidase important in CNS development through extracellular matrix remodeling and synaptic plasticity (Reinhard et al., 2015). Increased MMP-9 levels are seen in the \textit{Fmr1} KO mouse and FXS human brains (Bilousova et al., 2009; Dziembowska et al., 2013; Sidhu et al., 2014). Genetic reduction of MMP-9 levels in the \textit{Fmr1} KO mouse restored auditory cortex responses to WT levels (Lovelace et al., 2016; Wen et al., 2018), rescued dendritic spine abnormalities in the hippocampus and reduced anxiety-like behaviors (Sidhu et al., 2014). Beneficial effect of MMP reduction on synaptic arborization is seen in the dorsophila model of FXS (Siller and Broadie, 2011). Inhibition of MMP-9 with minocycline reduces multiple symptoms in the \textit{Fmr1} KO mouse and humans with FXS (Bilousova et al., 2009; Dziembowska et al., 2013; Schneider et al., 2013). However, it is not known if MMP-9 levels are high in circuits involved in sensorimotor gating (Li et al., 1998) and if reduction of MMP-9 in FXS reduces sensorimotor gating abnormalities. In this study, we focused on the inferior colliculus (IC) because this region of the midbrain is a main source of inhibition that causes PPI (Fendt et al., 2001). We found increased MMP-9 levels in the IC during development, but not in adults. The second aim was to determine if ASR and PPI responses in \textit{Fmr1} KO mice were different from WT mice from a young age. We found reduced PPI in the \textit{Fmr1} KO mice compared to WT mice in both age groups tested: young (P23-25) and adult. A genotype difference in ASR was found only in the young age group. Finally, we tested the hypothesis that genetic reduction of MMP-9 in \textit{Fmr1} KO mice would alleviate PPI abnormalities in the \textit{Fmr1} KO mice. For this purpose, we generated \textit{Fmr1} KO mice, which were heterozygous for MMP-9 and found that these mice show ASR and PPI responses that are comparable to the WT mice.

2. Results

2.1. Gelatin zymography for MMP-9 levels in the inferior colliculus

Gelatin zymography was used to measure MMP-9 levels in the IC of WT and \textit{Fmr1} KO mice at four different ages: postnatal day (P) 7, 12, 18, and 40. At P7 (t(4) = -2.47, p = 0.0345) and P12(t(7) = -2.054, p = 0.0395), \textit{Fmr1} KO mice showed greater MMP-9 levels compared to WT (Fig. 1). There was no genotype difference in MMP-9 levels at P18 (t (8) = -0.267, p = 0.398) and P40 (t(6) = -0.299, p = 0.772). These results show that as in the forebrain (Lovelace et al., 2016), loss of FMRP in the midbrain also causes an increase in MMP-9 levels.

2.2. Acoustic startle response and prepulse inhibition

The ASR was measured in young and adult mice. Young (P23-25) \textit{Fmr1} KO mice showed a significant reduction in ASR compared to age-matched WT mice (one-way ANOVA, \textit{F}(1,16) = 6.190, \textit{p} = 0.024) (Fig. 2A). To examine PPI, two-way ANOVA was used with prepulse intensity and genotype as factors. PPI was significantly reduced in young \textit{Fmr1} KO mice compared to WT mice (Genotype: \textit{F}(1,48) = 9.226, \textit{p} = 0.004) (Fig. 2B). While prepulse intensity affected PPI (Intensity: \textit{F}(2,48) = 3.267, \textit{p} = 0.047; Tukey HSD, 75 dB vs 85 dB, \textit{p} = 0.596; 75 dB vs 95 dB, \textit{p} = 0.038; 85 dB vs 95 dB, \textit{p} = 0.273), there were no significant interactions between genotype and prepulse intensity (Genotype * Intensity: \textit{F}(2,48) = 0.499, \textit{p} = 0.610). This suggests that the genotype difference in PPI is not due to change in any specific intensity tested.

The ASR was not different between adult (P50-80) WT, \textit{Fmr1} KO, and MMP-9+/−/\textit{Fmr1} KO mice (one-way ANOVA, \textit{F}(2,24) = 1.019, \textit{p} = 0.376) (Fig. 3A). A two-way ANOVA with genotype and prepulse intensity as factors showed that there was a main effect of genotype (\textit{F}(2,72) = 5.583, \textit{p} = 0.006), and prepulse intensity (\textit{F}(2,72) = 18.56, \textit{p} = 0.001), but no significant interactions (\textit{F}(4,72) = 0.401, \textit{p} = 0.807) (Fig. 3B). Post hoc Tukey HSD analyses revealed that \textit{Fmr1} KO PPI was significantly reduced compared to WT (WT vs. \textit{Fmr1} KO, \textit{p} = 0.004) as seen in the young mice. There was no difference in PPI responses between WT and MMP-9−/−/\textit{Fmr1} KO WT (WT vs. MMP-9−/−/\textit{Fmr1} KO, \textit{p} = 0.106). Additionally, prepulse intensity post hoc analysis revealed that as the sound intensity increased, the PPI increased as well (75 dB vs 85 dB, \textit{p} = 0.044; 75 dB vs 95 dB, \textit{p} = 0.00431, 85 dB vs 95 dB, \textit{p} = 0.267).

One potential methodological concern is that the mice show startle response to the pre-pulse, particularly at 85 and 95 dB SPL (Valsamis and Schmid, 2011). However, because the ASR itself was not different at this age, it is unlikely that the genotype PPI differences were due to startle to the pre-pulse. In addition, the genotype effects are present even if only the 75 dB SPL prepulse is considered, which is unlikely to cause startle by itself (one-way ANOVA analyses of PPI for the 75 dB prepulse (\textit{F}(2, 24) = 3.446, \textit{p} = 0.04). Taken together, these data indicate that genetic reduction of MMP-9 in the \textit{Fmr1} KO mice, provides a rescue of the PPI deficit, without impacting the baseline ASR.

2.3. Habituation

Habituation of electrophysiological response to repeated stimulation is reduced in both humans with FXS and the \textit{Fmr1} KO mice (Ethridge et al., 2016; Lovelace et al., 2016; Schneider et al., 2013). Genotype differences in ASR may arise due to differences in habituation to startle stimuli. Therefore, we examined whether ASR habituation is altered in the \textit{Fmr1} KO mice. Habituation was calculated by dividing the average of the final five ASR values by the average first five ASR values (see Methods). There was no genotype difference in habituation in young (\textit{F}(1,16) = 0.316, \textit{p} = 0.582) (Fig. 4A) or adult (\textit{F}(2,24) = 0.368, \textit{p} = 0.696) (Fig. 4B) mice. This suggests that in the young mouse, genotype differences in ASR do not occur because of altered habituation.

3. Discussion

We found that in young, but not in adult, \textit{Fmr1} KO mice, there was a significant reduction in ASR amplitude compared to age matched WT mice. In both age groups, PPI was significantly reduced in the \textit{Fmr1} KO mice compared to WT mice, suggesting that sensorimotor gating
abnormalities present in young Fmr1 KO mice are maintained into adulthood. We also found increased MMP-9 levels in the IC of the developing, but not adult, Fmr1 KO mice. This suggests that abnormal MMP-9 levels in the IC may be associated with reduced PPI. While WT and Fmr1 KO mice were significantly different from each other in terms of PPI, the MMP-9 +/−/Fmr1 KO mice were not different from either WT or Fmr1 KO mice. We interpret this to mean that there was a partial rescue of the PPI phenotype when MMP-9 was reduced in the Fmr1 KO

![Fig. 1. MMP-9 levels in IC differ between WT and adult Fmr1 KO mice at P7 and P12, but not P18 or P40. There was an increase in MMP-9 levels in Fmr1 KO mice earlier in development (P7: t(4) = −2.47, p = 0.0345; P12: t(7) = −2.054, p = 0.0395). However, at later ages there was no difference between the two genotypes (P18: P18 (t(8) = −0.267, p = 0.398); P40 (t(8) = −0.299, p = 0.772). Standard error is shown in the bar graphs.]

![Fig. 2. Startle is reduced in Fmr1 KO mice at young, but PPI is not different from WT. A) The baseline ASR was significantly different between young WT and Fmr1 KO mice (one-way ANOVA – F(1,16) = 6.190, p = 0.024). B) Two-way ANOVA with prepulse intensity and genotype as factors in the young mice revealed that PPI increased with sound intensity (Intensity – F(2,48) = 3.267, p = 0.047; Tukey HSD – 75 dB vs 85 dB, p = 0.596; 75 dB vs 95 dB, p = 0.038; 85 dB vs 95 dB, p = 0.273) and was reduced in Fmr1 KO compared to WT mice (Genotype – F(1,48) = 9.226, p = 0.004). There were no significant interactions between genotype and prepulse intensity (Genotype * Intensity – F(2,48) = 0.499, p = 0.610). Standard error is shown in the bar graphs.]

![Fig. 3. Genetic reduction of MMP-9 in Fmr1 KO mice partially rescues the PPI deficit. A) In adult mice, there was no statistical difference in ASR across the three genotypes (one way ANOVA – F(2,24) = 1.019, p = 0.376). B) Two way ANOVA with genotype and prepulse intensity as factors shows that in adult mice, there was a significant effect of genotype (F(2,72) = 5.583, p = 0.006; Tukey HSD – WT vs Fmr1 KO, p = 0.004; WT vs MMP9 +/− vs Fmr1 KO, p = 0.427; Fmr1KO vs MMP9 +/− Fmr1 KO, p = 0.106) and intensity (F(2,72) = 8.156, p = 0.001; Tukey HSD – 75 dB vs 85 dB, p = 0.044; 75 dB vs 95 dB, p = 0.000431; 85 dB vs 95 dB, p = 0.267), but no interactions (Genotype * Intensity – F(4,72) = 0.401, p = 0.807). Standard error is shown in the bar graphs.]
mice. The partial correction implies other mechanisms in the ASR/PPI pathway such as abnormal ion channel function may be involved in sensorimotor gating dysfunction in FXS (Deng et al., 2013; Zaman et al., 2017). The adult mouse data are consistent with data from humans with FXS who show no differences in ASR and reduced PPI suggesting that these sensorimotor gating measures can be used as potential biomarkers (Frankland et al., 2004; Hessl et al., 2009). Together these results strongly suggest that increased MMP-9 in FXS underlies abnormal sensorimotor gating and may cause sensory hypersensitivity. This conclusion is consistent with the findings of Gkogkas et al. (2014), who over-expressed MMP-9 in mice and found FXS-like symptoms.

ASR in Fmr1 KO mice has been examined by a number of groups, but the results are mixed in a manner indicating sensitivity of measures to variations in stimulus parameters, age, and genetic background. Chen and Toth (2001) showed that ASR is significantly reduced in 7–10 weeks old Fmr1 KO mice compared to WT mice on the FVB background. Yun et al. (2006) showed reduced ASR in Fmr1 KO mice compared to WT in FVB strain mice older than 4 weeks, but ASR was not different in mice younger than 3 weeks. In the C57B6/J genetic background, ASR was shown to be higher in the Fmr1 KO mice compared to WT for stimuli in the 70–80 dB range (Nielsen et al., 2002). However, when a 120 dB startle stimulus was used, the WT mice showed stronger ASR than the Fmr1 KO mice. Frankland et al. (2004) tested C57B6/J mice and found no difference in ASR for stimuli < 90 dB SPL. However, for > 95 dB SPL, ASR was stronger in the WT mice compared to Fmr1 KO mice. Ding et al. (2014) and Veeraragavan et al. (2011) showed no genotype difference in ASR. Together the preponderance of evidence suggest that ASR is either not different between the genotypes, or decreased in Fmr1 KO mice compared to WT. Our data are consistent with this trend, with young Fmr1 KO mice showing reduced ASR and adults showing no genotype difference, although the mechanisms for age-dependent genotype differences in ASR are unclear. There were no significant differences in average weight of mice between the two genotypes in either young or adult ages, suggesting that this is not a factor in the age effect on genotype difference in ASR. It is possible that the muscle tone is different in young mice. Largo and Schinzel (1985) suggested a developmental delay in motor function, with boys with FXS showing reduced muscle tone. But, very little is known about development of muscle function in the Fmr1 KO mice. Future studies should examine electromyographic responses in these mice to determine potential delays in muscle function. The difference between young and adult ASR responses should, however, not be surprising because developmentally transient genotype differences appear to a prominent feature in FXS (see Meredith et al., 2012 for a review).

Several studies have examined PPI in Fmr1 KO mice, also with mixed results. Chen and Toth (2001) showed PPI was increased in Fmr1 KO mice compared to WT (FVB background) at both 75 dB and 85 dB SPL prepulse intensities. The differences with our PPI result may arise from different protocols used in the two studies. We included all prepulse intensities in one session, whereas, Chen and Toth (2001) tested the lower intensity a month prior to testing the higher intensity. Nielsen et al. (2002), Frankland et al. (2004), and Ding et al. (2014) also reported increased PPI in Fmr1 KO mice on the C57B6/J background. Veeraragavan et al. (2011) reported no difference and De Vrij et al. (2008) used eye-blink response and reported decreased PPI in the Fmr1 KO mice. Despite this evidence suggesting increased PPI in the Fmr1 KO mouse, humans with FXS show significantly reduced PPI (Frankland et al., 2004; Hessl et al., 2009), which is consistent with our results.

A novel finding of this paper is that abnormal MMP-9 activity may underlie sensorimotor gating abnormalities in FXS. MMP-9 is one of the targets of FMRP, so with the absence of FMRP, there is an upregulation of MMP-9 (Dziembowska et al., 2013) in several regions of the brain in FXS. The ASR pathway consists of the auditory nerve input to the ventral cochlear nucleus, which connects to the caudal pontine reticular nucleus, from there synapsing onto the motor neurons of the spinal cord whose activity elicits the startle response (Koch and Schnitzler, 1997). We show here that MMP-9 levels are increased in the IC of Fmr1 KO mice as well. The IC is a major hub of both the ascending and descending auditory pathway, and is critically involved in PPI (Fendt et al., 2001). The activation of the IC by the prepulse sound is rapidly relayed as a long duration inhibition of the neurons of the pontine reticular nucleus neurons. The inhibition generated by the IC reduces ASR, leading to the classic PPI of startle response. Interestingly we found increased MMP-9 in the IC at P7 and P12, but not at P18 or P40. We found reduced PPI at ~P23 and ~P50, when MMP-9 levels in the IC are similar to WT. This suggests that MMP-9 plays a crucial role in the development of IC, and abnormalities in early development of IC are sustained into adulthood, even though MMP-9 levels are normalized. This makes the crucial prediction that any pharmacological treatment through MMP-9 manipulation to reduce sensorimotor gating abnormalities would be more effective if given during the P7-P12 window, rather than in adulthood. Future studies will test this prediction.

4. Conclusions

In findings similar to those seen in humans with FXS, we provide evidence for reduced PPI in the Fmr1 KO mice. PPI, may therefore, be developed as biomarker for pursuit of translation-relevant therapeutic avenues in FXS. Reduced PPI was seen in both adult and young Fmr1 KO mice, suggesting early developmental origin of sensorimotor gating abnormalities in FXS and the necessity to provide treatment early in development. Finally, our data suggest a potential target for reducing sensory hypersensitivity in FXS through a reduction of MMP-9 levels.
using specific inhibitors and at specific developmental time points.

5. Methods and materials

5.1. Mice

FVB.129P2 – Pde6b + Tys-/-/AntJ controls (WT) and FVB.129P2 – Fmr1tm1Cgr/J (Fmr1 KO) mice were received from Jackson Laboratories and housed on a 12:12 light/dark cycle, with standard lab chow and water given ad libitum in the vivarium. To generate the Mmp9+/−/Fmr1 KO mice, FVB.Cg-Mmp-9tm1Tvus/J mice were backcrossed with Fmr1 KO mice. These mice had a reduced expression of Mmp-9 in the auditory cortex (Sidhu et al., 2014; Wen et al., 2018). Genotypes of mice were verified by sending tail samples to Transnetyx (Cordova, TN). There were two age groups tested: young ("Y", PND 23-25) and adult ("A", PND 50-80). Table 1 provides information about the age and average weight of each group. Weights between genotypes were not significantly different in either the young (t(16) = 1.792, p = 0.092) or adult (F(2,24) = 0.71, p = 0.502) groups. All procedures were approved by the Institutional Animal Care and Use Committee at the University of California, Riverside. Each experimental group consisted of n = 9 mice. All mice tested were males.

5.2. Apparatus

The Coulbourn Animal Acoustic Startle System (Coulbourn Instruments, Whitehall, PA) was used to measure the ASR. The apparatus consisted of a single subject anechoic startle chamber with a ventilating fan built into the ceiling to provide background noise (68 dB SPL). A weight-sensitive startle platform was centered inside of the chamber. The A10-21B Startle Controller Software was used to generate the Mmp9+/−/Fmr1 KO mice, FVB.Cg-Mmp-9tm1Tvus/J mice were backcrossed with Fmr1 KO mice. These mice had a reduced expression of Mmp-9 in the auditory cortex (Sidhu et al., 2014; Wen et al., 2018). Genotypes of mice were verified by sending tail samples to Transnetyx (Cordova, TN). There were two age groups tested: young ("Y", PND 23-25) and adult ("A", PND 50-80). Table 1 provides information about the age and average weight of each group. Weights between genotypes were not significantly different in either the young (t(16) = 1.792, p = 0.092) or adult (F(2,24) = 0.71, p = 0.502) groups. All procedures were approved by the Institutional Animal Care and Use Committee at the University of California, Riverside. Each experimental group consisted of n = 9 mice. All mice tested were males.

5.3. Procedures

Mice habituated for 20 min in their home cages after being transported to the lab. Afterwards, each mouse was weighed, and allowed to habituate for 10 additional minutes in the holding cage, before being placed in the startle chamber. A five-minute delay was built into the program to allow the animal to acclimate to the chamber prior to the stimulus presentation. The built-in fan provided background noise of 68 dB SPL, measured with a digital sound level meter (BK Precision, Model 732A). Table 2 provides information on the various trials used. Trial type 1 consisted of the initial six and final five trials, which presented only 115 dB SPL startle stimulus. These trials were used to calculate the ASR and habituation. Between the stimulus alone trials, eight of each prepulse trials were presented in pseudorandom order, with the prepulse – 75, 85, or 95 dB SPL – preceding the startle stimulus by 100 ms. Duration of the prepulse sound was 20 ms and duration of the startle pulse was 40 ms. Additional prepulse trials were excluded from analysis, due to being of similar sound levels to the startle stimulus (105 dB). The inter-trial interval ranged from 15 to 25 s to minimize anticipation of the startle stimulus delivery.

5.4. Gelatin zymography

Inferior colliculus (IC) tissue samples were taken from P7, P12, P18, and P40 mice. The mice were euthanized with isoflurane, the IC was dissected and immediately flash frozen over dry ice then stored at −80 °C. The gelatin zymography protocol was performed as previously described in Wen et al., 2018. The zymography buffer used to resuspend the IC included 100 μL of 100 mM Tris-HCl (pH = 7.6), 150 mM NaCl, 5 mM CaCl2, 0.05% Brij35, 0.02% Na3N, 1% Triton X-100, 100 μM PMSF and protease inhibitor cocktail (Sigma, catalog# P8340). Gelatin agarose beads (Sigma, catalog# G5384) were added to the sample lysates to pull down MMP-9 on 10% Tris-Glycine gel with 0.1% gelatin as the substrate (Life Technologies). Once pulled down, the gels were then stained with Commassie blue overnight and de-stained for subsequent analysis. Total protein concentration was measured per lysate using the BCA colorimetric protein assay (Pierce, 23 235). Levels of MMP-9 protein were analyzed using Photoshop CS4. All samples were normalized to the WT values per each individual age group (n = 3–7).

5.5. Data analysis

Weight comparisons were done by independent t-tests to compare the young groups and one-way ANOVA was used to compare the adult groups. One-tailed unpaired t-test was used to compare WT and Fmr1 KO MMP-9 levels. ASR was calculated by averaging the peak magnitude of the startle stimulus alone responses and across the 11 Trial Type 1 responses. Percent habituation was calculated as % Habituation = 100 × (average last five Trial Type 1 responses/average first five Trial Type 1 response). Percent PPI was calculated as % PPI = 1-(average startle amplitude from prepulse trial/average startle amplitude from startle stimulus alone trial) × 100. To compare PPI across genotypes, a two-way ANOVA was used with prepulse intensity (75, 85, 95 dB) and genotype (KO, WT) as factors. One-way ANOVA was used for comparison of ASR across genotypes separately for each age group tested. Standard error is shown by the error bars in all figures. Age was not tested as a factor in any analysis. Post-hoc tests are as described in the Results section.
